## Standard Error Calculations for NPTS Estimates

These notes describe the table.sas SAS macro for computing standard errors for NPTS estimates. The macro is a modified version of tablew.sas, a SAS macro whose purpose is to do these standard error calculations as part of the NPTS web server online analysis package (see <http://www-cta.ornl.gov/npts/>). The macro can nevertheless also be used by others using SAS to compute NPTS estimates, and we are therefore making it available via the web server. Understand, however, that the macro was designed to support the web-server calculations and not as a general analysis package. It may not suit your particular purpose. The macro is distributed in the hope that it will be useful, but **without any warranty, without even an implied warranty of merchantability or fitness for a particular purpose.**

The notes are in three sections and three appendices. The first section is about the general theory behind standard errors and confidence bound calculations for estimates computed from NPTS data. Much of the discussion in the first section is from Appendix G of the *CENVAR Variance Calculation System User's Guide* (Bureau of Census 1995). The second section is about using the SAS table macro to do the calculations. The third section is an example. Appendix A consists of twelve more examples; the “Standard Tables” from the NPTS User’s Guide (FHWA 1997, Appendix B) are revisited. The SAS table macro itself is listed in Appendix B. Appendix C is a discussion of problems using subsets of the NPTS data (e.g., subsetting where clauses), and is included mainly to document the approach taken to subsetting where clauses in the web-server SAS macro tablew.sas.

The tablew.sas macro performs several functions peculiar to the requirements of the web-server analyses, and also does **not** compute several things table.sas does, for instance confidence intervals. However, tablew.sas can also be downloaded. It has code for formatting tables using the SAS tabulate procedure as a text formatter, and also for converting and formatting ‘All’ categories (coded with ‘.’s) in the table.sas output. Other than in Appendix C, however, tablew.sas will not be discussed further.

### 1. Standard Errors for NPTS Estimates Via the Ultimate Cluster Variance Formula

Standard errors in the SAS table macro are computed using the *ultimate cluster* variance formula (Hansen, Hurwitz, and Madow 1953). An ultimate cluster consists of the entire sample from the primary sampling unit—a household in the NPTS—from one or more stages of sampling.

**1.1. Estimators of Totals and Ratios.** Consider a sampling design with  $S$  strata, and, for each stratum  $s$  ( $s=1,\dots,S$ ),  $n_s$  primary sampling unit (PSUs). Let  $\mathbf{A}$  denote a class (e.g., males age 20-30), and  $y$ , a variable (e.g., miles driven) determined for each element of  $\mathbf{A}$ . Let  $A$  denote the set of indices  $j$  for elements of the class  $\mathbf{A}$ , and let  $y_{sij}$  denote the observed value of the variable  $y$  for element  $j$  in the  $i^{\text{th}}$  sample PSU in substratum  $s$ . Also let  $w_{sij}$  denote the final adjusted sampling weight—for all stages of selection—for element  $sij$ .

Then the estimator of the total  $Y_A$  of  $y$  in the class  $\mathbf{A}$  is

$$\hat{Y}_A = \sum_{s=1}^S \sum_{i=1}^{n_s} \hat{Y}_{Asi}, \quad (1)$$

where

$$\hat{Y}_{Asi} = \sum_{j \in A} w_{sij} y_{sij}.$$

The estimator of a ratio  $R = Y_A/X_B$  of a numerator total  $Y_A$  for a class **A** to a denominator total  $X_B$  for a class **B** is

$$\hat{R} = \frac{\hat{Y}_A}{\hat{X}_B}, \quad (2)$$

where  $\hat{Y}_A$  is the estimate of  $Y_A$ , calculated as in formula (1), and  $\hat{X}_B$  is the estimate of a total  $X_B$ , also calculated as in formula (1), for a variable  $x$  determined for each element of class **B**. In the SAS table macro, the class **A** is assumed to be either equal to or else a refinement of the class **B**. For example, **B** might denote males, and **A**, males, age 20-30.

Means and frequency proportions are special cases of ratios. For a mean, the classes **A** and **B** in (2) are the same, the variable  $x$  for the denominator of the ratio is the constant 1, and the total estimate  $\hat{X}_B$  is the sum of the sampling weights for all elements in class **A=B**. For a frequency proportion, the class **A** is ordinarily a strict subset of class **B**, and both the numerator and denominator variables  $x$  and  $y$  are 1 for all elements.

**1.2. Variances of Estimators of Totals.** From the probability model and from the definition of variance, it can be proved that the variance of an estimator of a total (1) under single-stage stratified sampling with replacement is

$$Var(\hat{Y}_A) = \sum_{s=1}^S \frac{1}{n_s} \sum_{i=1}^{N_s} p_{si} \left( \frac{Y_{Asi}}{p_{si}} - \bar{Y}_{As} \right)^2, \quad (3)$$

where  $N_s$  is the total number of PSUs in substratum  $s$  ( $n_s$ , as defined above, is the number of PSUs in the sample),  $p_{si}$  is the selection probability of the  $i^{\text{th}}$  PSU in substratum  $s$ ,  $Y_{Asi}$  is the population total of elements in the  $i^{\text{th}}$  PSU and class **A**, and

$$Y_{As} = \sum_{i=1}^{N_s} Y_{Asi}.$$

Similarly, it can be shown that if  $n_s > 1$  for all strata, then an unbiased estimate of the variance (3) is

$$v(\hat{Y}_A) = \sum_{s=1, n_s > 1}^S \left[ \frac{n_s}{n_s - 1} \sum_{i=1}^{n_s} \left( \hat{Y}_{Asi} - \frac{\hat{Y}_{As}}{n_s} \right)^2 \right]$$

(all terms defined as above). Strata with  $n_s = 1$  are also included in the calculation of  $\hat{Y}_A$ , however. For those strata, the  $n_s - 1$  denominator in the above variance estimate will obviously cause problems, and so, as an approximation,  $\hat{Y}_{As}^2$  is added to the variance estimate:

$$v(\hat{Y}_A) = \sum_{s=1, n_s > 1}^S \left[ \frac{n_s}{n_s - 1} \sum_{i=1}^{n_s} \left( \hat{Y}_{Asi} - \frac{\hat{Y}_{As}}{n_s} \right)^2 \right] + \sum_{s=1, n_s = 1}^S \hat{Y}_{As}^2. \quad (4)$$

The approximation, which is biased high, is good as long as there are not too many strata with  $n_s = 1$ .<sup>1</sup>

Unadjusted sampling weights are the reciprocals of the selection probabilities. The final sampling weights are adjusted, however, to account for statistical departures from known totals and to correct for design irregularities. For the NPTS, the weight adjustments account for households with more than one telephone number, constrain certain sums to known control totals (e.g., total number of persons), correct for nonresponse and non-coverage, and reduce nonresponse bias (FHWA 1997, Section 3G).

When there is subsampling, that is, a second, incomplete sampling stage, the variance of the total estimator exceeds (3) by a term that accounts for within-PSU components of variance. In the NPTS study, there was no subsampling. Nonresponse among individuals within households was possible, however, and the second stage is incomplete to the extent that there was nonresponse. This nonresponse is accounted for in the weight adjustments.

**1.3. Covariances of Estimators of Totals and Variances of Estimators of Ratios.** As with variances, it can be shown that the covariance of  $\hat{Y}_A$  and  $\hat{X}_B$  is

---

<sup>1</sup>The approximation is based on the inequality, for any random variable  $Z$ ,  $Var(Z) \leq Mean(Z^2)$ .

$$Cov(\hat{Y}_A, \hat{X}_B) = \sum_{s=1}^S \left[ \frac{1}{n_s} \sum_{i=1}^{n_s} p_{si} \begin{pmatrix} Y_{Asi} \\ p_{si} \end{pmatrix} \begin{pmatrix} X_{Bsi} \\ X_{Bs} \end{pmatrix} \right],$$

and if  $n_s > 1$  for all strata, an unbiased estimator is of  $Cov(\hat{Y}_A, \hat{X}_B)$  is

$$cov(\hat{Y}_A, \hat{X}_B) = \sum_{s=1}^S \left[ \frac{n_s}{n_s - 1} \sum_{i=1}^{n_s} \begin{pmatrix} \hat{Y}_{Asi} \\ \frac{\hat{Y}_{As}}{n_s} \end{pmatrix} \begin{pmatrix} \hat{X}_{Bsi} \\ \frac{\hat{X}_{Bs}}{n_s} \end{pmatrix} \right].$$

In practice, as an approximation to accommodate strata with  $n_s = 1$ , the covariance estimate is taken as

$$cov(\hat{Y}_A, \hat{X}_B) = \sum_{s=1, n_s > 1}^S \left[ \frac{n_s}{n_s - 1} \sum_{i=1}^{n_s} \begin{pmatrix} \hat{Y}_{Asi} \\ \frac{\hat{Y}_{As}}{n_s} \end{pmatrix} \begin{pmatrix} \hat{X}_{Bsi} \\ \frac{\hat{X}_{Bs}}{n_s} \end{pmatrix} \right] + \sum_{s=1, n_s = 1}^S \hat{Y}_{As} \hat{X}_{Bs}.$$

The covariance enters into the following approximation for the variance of the ratio, which is based on a Taylor expansion approximation:

$$Var(\hat{R}) = Var\left(\frac{\hat{Y}_A}{\hat{X}_B}\right) \approx \frac{1}{X_B^2} Var(\hat{Y}_A) - \frac{Y_A^2}{X_B^4} Var(\hat{X}_B) + 2 \frac{Y_A}{X_B^3} Cov(\hat{Y}_A, \hat{X}_B).$$

By substituting estimates for the variances and covariances, an estimate of  $Var(\hat{R})$  can be computed as

$$v(\hat{R}) = \frac{1}{\hat{X}_B^2} \left[ v(\hat{Y}_A) - \hat{R}^2 v(\hat{X}_B) - 2 \hat{R} cov(\hat{Y}_A, \hat{X}_B) \right].$$

This variance estimate can be used to compute approximate 95% confidence intervals for  $\hat{R}$  as in

$$\hat{R} \pm 1.96 \times var(\hat{R})^{1/2},$$

where 1.96 is the 97.5 percentile of the standard normal distribution. These bounds are approximate because they depend on (A) estimates of variances and the covariance, (B) the large-sample normality of  $\hat{R}$ , and (C) Taylor's approximation.

Alternatively, an approach due to Fieller (1932) is based on the observation that since  $R = \hat{Y}_A / \hat{X}_B$ , the expected value of  $\hat{Y}_A - R\hat{X}_B$  is 0. Because

$$P\left[\frac{(\hat{Y}_A - R\hat{X}_B)^2}{Var(\hat{Y}_A - R\hat{X}_B)} - 1.96^2\right] \approx .95,$$

and

$$Var(\hat{Y}_A - R\hat{X}_B) = Var(\hat{Y}_A) - R^2Var(\hat{X}_B) - 2Cov(\hat{Y}_A, \hat{X}_B),$$

substituting estimates for  $Var(\hat{Y}_A)$ ,  $Var(\hat{X}_B)$  and  $Cov(\hat{Y}_A, \hat{X}_B)$  gives

$$P\left[\hat{Y}_A^2 - R^2\hat{X}_B^2 - 2R\hat{Y}_A\hat{X}_B - 1.96^2v(\hat{Y}_A) - 1.96^2R^2v(\hat{X}_B) - 2 \times 1.96^2Rcov(\hat{Y}_A, \hat{X}_B)\right] \approx .95.$$

This is

$$P[aR^2 - bR - c = 0] \approx .95, \quad (5)$$

where  $a = \hat{X}_B^2 - 1.96^2v(\hat{X}_B)$ ,  $b = 2(1.96^2cov(\hat{Y}_A, \hat{X}_B) - \hat{Y}_A\hat{X}_B)$ , and  $c = \hat{Y}_A^2 - 1.96^2v(\hat{Y}_A)$ . Solving the quadratic equation for two real roots produces approximate 95% confidence bounds for  $R$ .<sup>2</sup> These

<sup>2</sup>It is possible, however, that the roots might imply a confidence region that is not an interval, or the roots might not exist at all. The table macro does not compute the Fieller-type confidence bounds in either of these cases. But these cases are unusual, as the following argument shows. The roots imply a confidence region that is not an interval if  $a < 0$ . This is unlikely as long as the relative variance of  $\hat{X}_B$  is not large, which becomes certain as the sample size increases. The condition  $a < 0$  in fact implies  $\hat{X}_B$  is not significantly different from 0, here, at the significance level .05.

The roots do not exist if  $b^2 - 4ac < 0$  (i.e., the quadratic equation has no real roots). Let  $s_y = v(\hat{Y}_A)^{1/2}$ ,  $s_x = v(\hat{X}_B)^{1/2}$ ,  $r = cov(\hat{Y}_A, \hat{X}_B)/s_y s_x$ ,  $t = 1.96$ , and assume  $\hat{Y}_A$  and  $\hat{X}_B$  are both positive or both negative. The opposite-sign case is similar. Then with a little algebra it may be shown that  $b^2 - 4ac$  is

$$4t^2s_x^2s_y^2 \left[ \left(r - \frac{\hat{X}_B\hat{Y}_A}{s_x s_y}\right)^2 - \left(\frac{\hat{X}_B}{s_x} - \frac{\hat{Y}_A}{s_y}\right)^2 - \left(1 - \frac{\hat{X}_B\hat{Y}_A}{s_x s_y}\right)^2 \right].$$

bounds are approximate because they depend on (A) estimates of variances and the covariance, and (B) the large-sample-approximate normality of  $\hat{Y}_A - R\hat{X}_B$ . They do not depend on Taylor's approximation. Notice that the normal approximation applies to the distribution of  $\hat{Y}_A - R\hat{X}_B$  rather than  $\hat{R}$ , as in the Taylor approximation approach. Cochran (1977) notes "This approach requires fewer assumptions than the normal approximation [to the distribution of  $\hat{R}$ ] and takes some account of the skewness of the distribution of  $\hat{R}$ ."

## 2. Computing Standard Errors with the SAS table Macro

To use the SAS table macro, first be sure that SAS can find it. Either include it directly in your SAS code, or use the mautosource option and the appropriate macro path, for example, as in

```
options mautosource SASAUTOS=(." "c:\bin" "c:\Programs\SAS\core\sasmacro");
```

Also before using the macro, the SAS library containing the NPTS formats catalog should be defined using a SAS libname statement (e.g., libname LIBRARY 'd:\npts\data');

The table macro is not designed to handle missing values or subsetting where clauses.<sup>3</sup> **Delete missing, logically excluded, or otherwise unwanted observations before using the macro.** Also ensure that missing values are reasonable in the first place. For example, suppose for a particular household, a particular variable is missing for every person. Then the household should probably also be regarded as missing, and that households should generally not contribute to the denominator of an estimate of the variable's per-household average. For ratios, the number of households for numerator and denominator variables should generally be the same.

For any particular analysis variable, the sample number of households in each substratum might depend on missing values of that variable. What if the analysis variable is missing for one person in a particular household, but not for another? Strictly speaking, adjustments for non-response to final weights should be tailored to the missing value structure of the particular analysis variable. No nonresponse adjustments to weights are made in the table macro, however, other than those already incorporated into the NPTS final adjusted weights. The final adjusted weights can be used as an approximation, but the approximation may be poor if there are a lot of missing values.

Even though there is a corresponding upper level (e.g., person) observation for every lower-level (e.g., trip) observation, missing upper-level values may entail deleting **lower**-level observations. For example, in computing trips per person for females and males, if the sex of a person is missing, then both the trip and person-data for that person would ordinarily be deleted. (Because of the way the

For unconstrained  $r$ , this is minimized where  $r = \hat{X}_B \hat{Y}_A / s_x s_y$ , which is ordinarily large and positive. However, because  $|r| \leq 1$  (Cauchy-Schwarz inequality), the minimum for  $|r| \leq 1$  typically occurs where  $r = 1$ , at which point  $b^2 - 4ac$  is positive.

Thus  $b^2 - 4ac$  tends to be positive in general.

<sup>3</sup>The tablew.sas macro does do this for the specially prepared data NPTS sets used by the web server.

table.sas macro handles missing values, these would be deleted anyway.)

To use the table macro, a SAS data set containing a variable *nhouse*, the number of households in each stratum (varstrat) and substratum (substrat), must be prepared and entered as a macro argument (see Table 1). If no households are excluded because of missing values or logical subsetting, then that data set can easily be computed from the household data set (hhold95). If, however, households are excluded by a subsetting “where” clause or because of missing values, then the number of households in a given substratum may be smaller than the total number of households for the entire survey, for that substratum.

In preparing the *nhouse* data set, also remember that higher-level variables might not be represented in lower-level data. For example, not every person need take a trip; not every household necessarily has a vehicle, or a female. It may be necessary to merge lower-level (e.g., trip) data with higher-level (e.g., person or household) data to ensure that these “no-shows”—households not logically excluded but not represented in the lower level data—are properly counted.

The table macro is called as

```
%table(outdata, indatay, ywt, yvar, rowvar, colvar, pagevar,  
      indatax, xwt, xvar, RCPx, rowfmt, colfmt, pagefmt, nhouse);
```

The macro creates a SAS data set *outdata*, which is the only output argument. The macro can compute a weighted mean—the ratio of a weighted analysis variable sum to the corresponding sum of weights. Frequency proportions can be computed either by making the *y* analysis variable an indicator, or by using both *y* variables (class **A**) and *x* variables (class **B**). If *yvar* is not entered, it is assumed to be identically equal to 1.

Table 1 defines the other input arguments. Optional arguments may be missing, but there must always be 14 delimiting commas. Input data sets are unchanged on output. The SAS missing variable code ‘.’ or ‘’ is not admitted for defining a legitimate class (i.e., is dropped in proc means): Use something like 999 for missing values instead. (This is because proc means generates its own ‘.’ values for the “All” categories.)

Table 2 lists the variables in the output data set created with the table macro. Not all variables are necessarily created (depending on optional inputs). These variable names are reserved words; they should not be used as macro arguments. The output variables listed in italics are arguments, the names supplied by the user. Names not in italics are the actual names of the output variables. Note that there is an output variable *xvar* (no italics) as distinguished from the input argument *xvar*.

The ratio lower confidence bounds are allowed to be negative to accommodate cases when numerators may be negative. If the LCBs turn out negative when they are logically nonnegative, set them to zero. But if ratio estimate **denominators** turn out nonpositive, ratio estimates and variances are not computed. Further, Fieller confidence bounds are not computed if either  $a < 0$  or  $b^2 - 4ac < 0$  (no real roots) in the quadratic equation (5) (see Section 1).

### 3. Examples

Running the SAS code in Exhibit 1 first creates formats for trip purpose and age category. It then creates a SAS data set *person* and a SAS data set *trip* from the original NPTS SAS data sets *person95* and *daytrp95*, in the SAS library ‘npts’. Age is broken into nine classes, including an “unknown” class. Trip purpose is recorded in the NPTS SAS variable *whytrp90*. No observations are excluded or missing. Notice that the class variable *whytrp90* is at the trip level, which is lower than the level of person, to which the age class variable applies.

Because no observations are missing or excluded, the data set *nhouse* containing the household counts for each stratum (*varstrat*) and substratum (*substrat*) are computed simply as frequency counts in the NPTS household level SAS data set *hhold95* (also in the NPTS SAS library).<sup>4</sup>

The data sets *person95* and *daytrp95* and the *nhouse* data sets are used as arguments to the table macro, which is used to estimate age-specific average trips per person for each trip purpose. The output of the example (Exhibit 1), which is simply a “contents” listing and a printout of the SAS data set created by the macro, is in Table 3a and 3b. Note that some of the variable labels are incomplete (truncated). This is because the labels are created automatically from labels of input variables, and because of the SAS limit for forty characters in labels. Macro users may need to redefine labels for variables with labels produced automatically.

Twelve more examples are in Appendix A. These are the Standard Tables from Appendix B of the NPTS *User’s Guide* (FHWA 1997). Both programs and output are in the appendix. The macro used to produce this version of the Standard Tables was exactly the same as *table.sas*, except (1) the output data set was suppressed (not needed), and (2) additional code was added to handle the ‘All’ categories and to format the tables using the SAS tabulate procedure.

Although the standard errors in the versions of Standard Table 1 and 3 produced here coincide exactly with the standard errors in Standard Tables 1 and 3 in the *User’s Guide*, the other standard errors differ slightly. This is because of the way “no-shows” were handled. For example, for Standard Table 6 (travel day person trips by age and sex), the input day-trip data contains no entries for persons (or households) with no trips. Persons without trips do not contribute to the count totals, but they do affect the standard errors, which depend on the total number of households in each substratum, including those with no trips. (See equation (4). The dependency is through  $n_s/(n_s - 1)$ , which increases in  $n_s$ . When households are undercounted, standard errors are too small.) The “no-shows” were not counted in the *User’s Guide* Standard Table 6; thus the discrepancy.

There is no discrepancy in the standard errors for Standard Table 1 (number of households by household income and number of vehicles), because all households are represented in the input household data set. The standard errors in the two versions of Standard Table 2 (number of vehicles by age and type) differ, however, because of households without vehicles, which are not represented

---

<sup>4</sup>e.g., proc freq data=npts.hhold95; table substrat/noprint out=a (drop=percent rename=(count=nhouse)); by varstrat;

**Table 1. Input arguments to SAS table macro\***

Argument	Description	Necessary/Optional?
<i>indatay</i>	input data set containing y variables. Must be sorted by varstrat substrat houseid.	Necessary
<i>ywt</i>	y variable weight—assumed nonmissing	Necessary
<i>yvar</i>	y analysis variable. Assumed equal to 1 if not entered.	Optional
<i>rowvar</i>	first class variable (defines rows)	Optional, but necessary if colvar is defined
<i>colvar</i>	second class variable (defines columns)	Optional, but necessary if pagevar is defined
<i>pagevar</i>	third class variable (defines pages)	Optional
<i>indatax</i>	input data set containing x variables. Must be sorted by varstrat substrat houseid. May be same as <i>indatay</i> .	Optional
<i>xwt</i>	x variable weight—if defined, assumed nonmissing	Optional but necessary if <i>indatax</i> is defined.
<i>xvar</i>	x analysis variable. Assumed equal to 1 if not entered, but <i>xwt</i> is.	Optional
<i>RCPx</i>	subset of rowvar colvar pagevar to define denominator classes. RCPx must be formable by deletion of zero or more entries in the rowvar colvar pagevar list.	Optional
<i>rowfmt</i>	name of user-supplied format for row variable (to override default)	Optional
<i>colfmt</i>	name of user-supplied format for column variable (to override default)	Optional
<i>pagefmt</i>	name of user-supplied format for page variable (to override default)	Optional
<i>nhouse</i>	SAS data set containing varstrat, substrat, and number of households in each substratum. Must be sorted by varstrat and substrat.	Necessary

\**outdata* is the only output argument. See text for discussion.

**Table 2. Variables in output data set (*outdata*) created with table macro\***

Output variable	Description
<i>ywt</i> <sup>†</sup>	Sum of input y-weights
<i>yvar</i> <sup>†</sup>	Weighted sum of input y variables
<i>rowvar</i> <sup>†</sup>	Same as input
<i>colvar</i> <sup>†</sup>	Same as input
<i>pagevar</i> <sup>†</sup>	Same as input
<i>xwt</i> <sup>†</sup>	Sum of input x-weights
<i>xvar</i>	Weighted sum of input x variables
<i>ny</i>	Number of observations with a <i>yvar</i> , or, if no <i>yvar</i> , then a <i>ywt</i>
<i>nx</i>	Number of observations with an <i>xvar</i>
<i>std_erry</i>	Standard error of <i>yvar</i> total
<i>se_ywt</i>	Standard error of <i>ywt</i> total
<i>std_errx</i>	Standard error of <i>xvar</i> total
<i>ratioy</i>	Ratio of <i>yvar</i> total to <i>ywt</i> total
<i>ratiox</i>	Ratio of <i>yvar</i> total to <i>xvar</i> total
<i>se_raty</i>	Standard error of <i>ratioy</i> , based on Taylor approximation
<i>se_ratx</i>	Standard error of <i>ratiox</i> , based on Taylor approximation
<i>corry</i>	Weighted correlation of <i>yvar</i> and <i>ywt</i>
<i>corr<sub>x</sub></i>	Weighted correlation of <i>yvar</i> and <i>xvar</i>
<i>lcb_fy</i>	Lower of Fieller-type 95% two-sided confidence bounds for <i>ratioy</i>
<i>ucb_fy</i>	Upper of Fieller-type 95% two-sided confidence bounds for <i>ratioy</i>
<i>lcb_fx</i>	Lower of Fieller-type 95% two-sided confidence bounds for <i>ratiox</i>
<i>ucb_fx</i>	Upper of Fieller-type 95% two-sided confidence bounds for <i>ratiox</i>
<i>lcb_tx</i>	Lower of Taylor-type 95% two-sided confidence bounds for <i>ratioy</i>
<i>ucb_tx</i>	Upper of Taylor-type 95% two-sided confidence bounds for <i>ratioy</i>
<i>lcb_ty</i>	Lower of Taylor-type 95% two-sided confidence bounds for <i>ratiox</i>
<i>ucb_ty</i>	Upper of Taylor-type 95% two-sided confidence bounds for <i>ratiox</i>

\*Not all variables are necessarily created.

<sup>†</sup>Italicized names are argument names. Other names are actual names.

## **Appendix B. SAS Standard Error Macro (table.sas)**

```

%macro table(outdata,indatay,ywt,yvar,
rowvar,colvar,pagevar,
indatax,xwt,xvar,RCPx,rowfmt,colfmt,pagefmt,nhouse);

/*
SAS macro for computing summary statistics and standard
errors from NPTS.

NOTE: THIS DRAFT MACRO IS NOT READY FOR PUBLIC RELEASE.

NOTE: This program is distributed in the hope that it will
be useful, but WITHOUT ANY WARRANTY, without even an
implied warranty of MERCHANTABILITY or FITNESS FOR A
PARTICULAR PURPOSE.

AUTHOR: Rick Schmoyer (ric@ornl.gov)

ACKNOWLEDGEMENT: Thanks to Jenny Young for finding bugs.

ARGUMENTS:
outdata=output data set. Necessary.

indatay=input data set containing y variable (yvar). Necessary.
MUST BE SORTED BY VARSTRAT SUBSTRAT HOUSEID;
Unchanged on output.

ywt=weight for numerator variable in ratio (if xwt defined). Necessary.
yvar=analysis variable for numerator in ratio. Optional.

rowvar=first class variable (defines rows). Optional,
but necessary if colvar is defined.

colvar=second class variable (defines columns). Optional,
but necessary if pagevar is defined.

pagevar=third class variable (defines pages). Optional.

indatax=input data set containing x variable (xvar). Optional,
but MUST BE SORTED BY VARSTRAT SUBSTRAT HOUSEID. Can be the same
as indatay. Unchanged on output.

xwt=weight for denominator in ratio. Optional.

xvar=analysis variable for denominator in ratio. Optional.

RCPx=subset of rowvar colvar pagevar to define denominator classes.
RCPx must be formable by deletion of zero or more entries
in the rowvar colvar pagevar list. Optional.

rowfmt=name of user-supplied format for row variable (to override default)

colfmt=name of user-supplied format for column variable (to override default)

pagefmt=name of user-supplied format for page variable (to override default)

nhouse=SAS data set with variables varstrat (stratum)
substrat (substratum) and nhouse (number of households).
nhouse must be computed from a proper count of households
not excluded by a subsetting where or because of missing
data (e.g., trips for that household, but trip variables of
interest all missing). Household counts should not exclude
variables simply because they are not represented in indatay
(e.g., no trips for a household does not automatically imply
the household should not be counted).

NOTE: Class variable code '.' is not admitted (i.e., is
dropped in proc means). Use something like 999 instead.

```

(Further, proc means does generate '..' values for the All categories.)

NOTE: Formats entered implicitly along with data must be in library 'LIBRARY'. Formats entered explicitly as macro arguments must be in default work library.

NOTE: Must have mautosource options and SASAUTOS= defined right to call SAS system macros (see sasautos).

OUTPUT VARIABLES in outdata ('&' denotes macro argument):

NOTE: THESE VARIABLE NAMES ARE RESERVED WORDS.

&rowvar	Same as input
&colvar	Same as input
&pagevar	Same as input
&yvar	If &yvar is not blank then weighted sum of input &yvar. If &yvar is blank, then macro variable yvar is reassigned value &ywt, and &yvar becomes sum of &yvar (&ywt).
&ywt	Sum of input &ywt
xvar	If &xvar is blank then macro variable xvar is reassigned value &xwt. Then &xvar is renamed to xvar. This avoids problem when &xvar=&yvar or &xwt=&ywt.
ny	Number of observations with a &yvar, or, if no &yvar, then &ywt
nx	Number of observations with an xvar
std_erry	Standard error of &yvar total
se_ywt	Standard error of &ywt total
std_errx	Standard error of xvar total
ratiox	Ratio of &yvar to xvar totals
ratioy	Ratio of &yvar to &ywt totals
se_ratx	Standard error of ratiox--based on Taylor approximation
se_raty	Standard error of ratioy--based on Taylor approximation
se_ratx1	Standard errors of ratios when ratio denominator   is FIXED, as when denominator is a control total
corrx	Weighted correlation of xvar and &yvar
corry	Weighted correlation of &yvar and &ywt
lcb_fx	Lower and Upper Fieller-type 95% two-sided confidence   bounds for ratio estimates (see Fieller E. (1932), "The   distribution of the index in normal bivariate populations,"   BIOMETRIKA, 24, 428-440) based on se_ratx and se_raty.
ucb_fx	
lcb_fy	
ucb_fy	
lcb_tx	
ucb_tx	Lower and Upper 95% two-sided confidence bounds for   ratio estimates, based on Taylor approximation for   variance of ratio. Based on se_ratx and se_raty.
lcb_ty	
ucb_ty	

NOTE: Ratio LCBs are allowed to be negative to accommodate cases when numerators are negative. If they turn out negative when they are logically nonnegative, set them to zero. But if ratio estimate DENOMINATORS turn out nonpositive, ratio estimates and variances are not computed. Further, Fieller confidence bounds are not computed if (1) denominators are not SIGNIFICANTLY different from zero, which occurs when when A < 0 in quadratic equation Az\*\*2 + Bz + C = 0 for confidence bounds (i.e., roots are confidence bounds--see below), or (2) when modulus B\*\*2 - 4AC is

```

negative (no real roots).

NOTE: Confidence bounds are based on normal approximation.

## Appendix C. Standard Error Computation with Subsets of the NPTS Data

Standard errors for NPTS estimates depend on the numbers of households represented in the estimates. It is therefore necessary that subsetting statements like “where state eq ‘AL’” or “where sex eq ‘F’” are properly accounted for in the standard error calculations. A subsetting restriction like “where state eq ‘AL’”, for example, reduces the number of households considered, but “where sex eq ‘F’” typically would not exclude households (unless perhaps the intent was to exclude households with only males). Ordinarily “where sex eq ‘F’” would simply indicate that results for males should not be counted in the tabulations, and not that any households should be excluded from the sample.

This appendix describes the approach taken in the web server macro tablew.sas to inferring from subsetting where statements, the correct number of households for the analysis. If a where statement component involves only household level variables (e.g., “where state eq ‘AL’”), call it a household (HH) level component. If a where statement component involves only lower level data variables (e.g., “where sex eq ‘F’”), call it a lower level (LL) component. Call a where statement component mixed if it combines both HH and LL components, as in “where state eq ‘AL’ and “sex eq ‘F’”. Inferring the correct interpretation can become especially complicated when the subsetting restrictions are mixed.

If we assume that LL components should not exclude households, then one approach to handling mixed where statements would be to set LL components to TRUE, so that, effectively, only HH components remain, and the modified where statement would consist entirely of HH components. The households excluded by the modified where statement would then not be counted when computing standard errors. However, a hitch in implementing this approach is the “NOT” operator. Because any where statement component can be modified by a NOT operator, for the approach of setting LL components to TRUE to work, NOTs must first be distributed over compound expressions.<sup>1</sup>

Furthermore, because it is generally not feasible to check that various where statement components are sensible, the approach of setting LL components to TRUE cannot guarantee the correct interpretation of the where statement. Thus the intent of “where sex eq ‘F’” could possibly be to exclude households with only males. Though not exactly sensible, a where statement such as “where state eq ‘AL’ or (state ne ‘AL’ and sex eq ‘Z’)” could (assuming it’s not a typo) be interpreted as an implicit attempt to exclude Alabama households. If “sex eq ‘Z’” is simply set to TRUE, the result is “where state eq ‘AL’ or state ne ‘AL’”, which would not exclude anything. But the user’s

---

<sup>1</sup>For example, suppose the intent is to compute totals for females from Alabama. This could be expressed as “where state eq ‘AL’ and sex eq ‘F’”. In that case, the approach of setting the sex eq ‘F’ component to TRUE would work: The expression reduces to “where state eq ‘AL’,” and so only households from Alabama would be included in the analysis. However, the same where statement can also be written as “where NOT (state ne ‘AL’ or sex ne ‘F’)”. With this where statement, the “sex ne ‘F’” component should not be set to TRUE, because “where NOT (state ne ‘AL’ or TRUE)” is (by De Morgan’s law) the same as “where state eq ‘AL’ and FALSE,” which is always false, and thus all households would be excluded. Instead, the NOT should be distributed over the compound expression in parenthesis to give “where (NOT state ne ‘AL’) and (NOT (sex ne ‘F’))”. Then, setting the “NOT (sex ne ‘F’)” component to TRUE gives “where NOT (state ne ‘AL’)\”, or simply “where state eq ‘AL’.” Because of the unlimited potential complexity of where statements, this distribution of NOTs should be recursive.

**intentions** here cannot be inferred with certainty.

Because of problems like these, the tablew.sas macro (and web interface) handles user-supplied where statements as follows. If the statement is HH (not mixed), it is assumed to exclude households from the sample. If it is LL, it is assumed to exclude observations from the tabulations, but not from the sample. If the where statement is mixed, then the macro requires that the user explicitly distinguish which households should be used in the analysis by supplying a HH statement to define the subset of observations to be used. LL components are assumed not to exclude households from the sample.

A user who is uncomfortable with this approach to handling where statements can download the NPTS data sets and the SAS macro, subset the data before inputting it to the SAS macro, and run the macro without a where statement. This will guarantee that exactly those households the user intends to include, will actually be included.
